(2020): Formation of the $[\text{Ge}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}]^{20+}$ Tetramer from Condensation of ϵ -GeAl₁₂ Keggin Polycations. ChemRxiv. Preprint. <https://doi.org/10.26434/chemrxiv.12910130.v1>

Keggin-type polyaluminum cations belong to a unique class of polyoxometalates (POMs) with their large positive charge, hydroxo bridges, and divergent isomerization/oligomerization. Previously reported oligomerizations of the polyaluminum cations were driven solely by the δ -Keggin isomer, which created Al_{26} , Al_{30} , and Al_{32} dimeric species. We herein report the isolation of largest ever Keggin-type structure for this system through a unique mode of self-condensation among four ϵ -GeAl₁₂⁸⁺ to form $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}]^{21+}(\text{Ge}_4\text{Al}_{48})$. Elemental analysis confirms the Ge⁴⁺ substitution, and dynamic light scattering experiments indicated that these larger species exist in the thermally aged solutions. DFT calculations have revealed that a single atom Ge substitution in tetrahedral site of ϵ -Al₁₃⁷⁺ is the key for the formation this cluster because it activates the deprotonation at certain octahedral sites to assist self-condensation in a specific mode.

1. Experimental Details

Synthesizing $\text{Ge}_4\text{Al}_{48}^{+20}$ and Crystallizing $\text{Na}[\text{Ge}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}](2,6\text{-NDS})_7\text{Cl}_7(\text{H}_2\text{O})_{45}$

All chemicals, $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$ (Fisher Scientific), NaOH (Fisher Scientific), GeO_2 (BeanTown Chemicals), and 2,6-naphthalenedisulfonate disodium salt (97%, Sigma Aldrich), were used as received. Aqueous solutions in this study used ultrapure water (18.2 M Ω .cm, Easypure II) as the solvent. A solution contains $\epsilon\text{-GeAl}_{12}$ was prepared by following general methodology of Lee et al., 2001 with some additional modification.¹ In a typical synthesis, 0.05 g of GeO_2 powder was added to 48 mL of a 0.25M NaOH solution and stirred until the solid was completely dissolved in the aqueous phase. This Ge^{4+} stock solution was heated to 85 °C and titrated with a 20 mL aliquot of a 0.25M AlCl_3 solution. After cooling to room temperature, 10 mL of this partially hydrolyzed $\text{Ge}^{4+}/\text{Al}^{3+}$ stock solution was loaded into a 23 mL Teflon-lined Parr reaction vessel and aged in a gravimetric oven set at 90 °C for 7 days. This thermally aged solution was again allowed to slowly cool to room temperature and then a 4 mL aliquot was added to a glass scintillation vial. To create high-quality single crystals, a 2.6 mL of 2,6-naphthalenedisulfonate solution (0.1M) was added to the vial, covered with perforated parafilm and allowed to slowly evaporate. After about 7 days, colorless, blocky crystals of $\text{Ge}_4\text{Al}_{48}$ were formed alongside amorphous flocculants. The yields of the crystalline phase was determined by mechanical separation and was determined to be approximately 15% based upon Al. We evaluated other crystallizing agents (K_2SO_4 , Na_2SeO_4 and 2,7-naphthalenedisulfonate) over the course of this study, but only isolated the previously reported $\epsilon\text{-GeAl}_{12}$ with Na_2SeO_4 (Space group = $I \bar{4} m2$, $a = 13.002(4)$, $b = 17.235(4)$, $\alpha = 90^\circ$).¹ However, the $\text{Ge}_4\text{Al}_{48}$ compound could be reproducibly formed using the protocol described above.

Structural Characterization by Single Crystal X-ray Diffraction (SCXRD)

A small (80 μm x 60 μm x 20 μm), but high-quality single crystal was separated from solvent using a needle with help of microscope and instantly coated in mineral oil on a MiTeGen micromount. The crystal was mounted in a Bruker D8 Quest single-crystal diffractometer equipped with a microfocus X-ray beam (Mo $\text{K}\alpha$; $\lambda = 0.71073 \text{ \AA}$) and a CMOS detector. Diffraction frames were collected at 100K (Oxford low-temperature cryosystem) with the Bruker APEX3 software package.² Peak intensities were corrected for Lorentz polarization, background effects, and absorption effects using the APEX3 software.² Initial structure solution was determined by intrinsic phasing and refined on the basis of F^2 for all unique data using the SHELXL 5 program.³ The disordered solvents (H_2O) was modeled using SQUEEZE command in the Platon software during structure refinement⁴. Metal atoms and most of the oxygens in $\text{Ge}_4\text{Al}_{48}$ cluster could be refined anisotropically. Hydrogen atoms associated with the 2,6-NDS and solvent molecules could not be assigned due to presence of disorder and partial occupancy.

Elemental Analysis by Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

The concentration of Al, Ge and their molar ratio in $\text{Ge}_4\text{Al}_{48}$ were determined in a Agilent 7900 ICP-MS system. A small amount (~5mg) $\text{Ge}_4\text{Al}_{48}$ crystals were separated from the

amorphous flocculant by hand from three different crystallization replicates was dissolved separately in 2% nitric acid solution. A series of Al and Ge standard solutions were prepared in 2% nitric acid by diluting 1000 ppm ICP-MS standards bought from Fluka Analytical. Calibration curves constructed from standard solutions were used to determine the Ge:Al ratio of the dissolved crystalline materials and analysis was performed in triplicate.

Table S1: ICP-MS result of 2% nitric acid digested $\text{Na}[\text{Ge}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}](2,6\text{-NDS})_7\text{Cl}_7(\text{H}_2\text{O})_{45}$ crystals.

Dynamic Light Scattering (DLS) measurement

The GeAl_{12}^{8+} aqueous solution was aged at 90 °C for 7 days, cooled to room temperature and then the colloidal phase was allowed aggregate to the bottom of the vial. After 48 hours, the clear solution from top was filtered through a 0.25 μm membrane filter for dynamic light scattering measurement to determine hydrodynamic diameter using Zetasizer Nano ZS (Malvern instrument ltd, MA).

Computational Methodology

To better understand the differences in Keggin isomers, aqueous models of the ϵ - and δ - MAl_{12} ($\text{M} = \text{Al, Ga, Ge}$) Keggin nanoclusters were studied using density functional theory (DFT) as implemented in the DMol³ quantum package developed by Delley.⁵⁻⁶ Experimental crystal structures of ϵ - GeAl_{12}^{8+} were obtained from Lee *et al.*;¹ ϵ - Al_{13}^{7+} from Parker *et al.*;⁷ δ - Al_{13}^{7+} from Son *et al.*;⁸ and $\text{Ge}_4\text{Al}_{48}^{20+}$ presented here. The experimental structures were used to create isolated molecular models, with hydrogen placement determined by bond valence to fulfill bonding requirements and stoichiometry. As previously used to study aluminum oxide nanomaterials,⁹⁻¹² aperiodic all-electron calculations were performed using the using the GGA-PBE¹³ level of theory, using the double-numeric polarized (DNP) atom-centered basis set and a real-space global cutoff of 4.5 Å. Optimization of all structures was done with an energy convergence criteria of 0.0003 eV and a residual force criteria of at least 0.005 eV/Å on all atoms. The Keggin models were embedded in the conductor-like screening model (COSMO) to simulate aqueous solvent effects.¹⁴

Previous computational studies have benchmarked the methods employed here. In computing cluster energetics, DMol³ relative energies at the PBE/DNP/COSMO level were compared to those obtained using Gaussian09 PBE0/TZVP/PCM for Al_{30} Keggin-type clusters containing 2 symmetry-equivalent Cu cations. As reported in Abeysinghe et al. 2013, the relative energies of $\text{Cu}_2\text{-Al}_{30}$ configurations differed between the two methods by 0.1 eV (or 4×10^{-4} eV/atom) for

clusters consisting of 238 atoms (2 Cu, 30 Al, 94 O, and 112 H)¹⁵. Additional testing compared the relative energies of GaAl₁₂ clusters, with varied positions of Ga, calculated at the PBE and B3LYP level (all other computational details consistent). The results showed maximum energy differences within 0.1 eV between different and optimized tetrahedral Ga-O bond lengths within numerical precision of one another. As such, the GGA-PBE functional is an appropriate functional choice for studying these oxyhydroxide clusters in terms of balancing computational cost and accuracy. Testing was also done to compare how basis set quality influences relative energies of two Al₁₃ isomers, comparing the polarized double (DNP) and triple-numeric (TNP) basis sets.¹⁶ The energy difference between the ϵ - and δ -isomers was found to be 0.072 eV for DNP and 0.086 for TNP; as the computed differences in relative energy are of a similar magnitude, it can be concluded that DNP is a suitable choice in basis set.

Calculations of the isolated ϵ - and δ -MAl₁₂ nanoclusters were used to compare relative stability of the isomers, where M= Al or Ge. Interactions of ϵ -Al₁₃ and ϵ -GeAl₁₂ with SO₄²⁻ were sampled, taking note of instances where the anion interaction resulted in cluster deprotonation. The change in Mulliken charge population (Δq_M) provides a metric for comparing charge transfer or the degree of electron sharing between the Keggin and the anion, given in units of fundamental electron charge (e). Values of Δq_M are calculated by summing the partial atomic charges of the sulfate anion and determining the change from the initial formal charge of -2 e. Previous studies have shown that interactions resulting in anion Δq_M values greater than 0.50 e undergo deprotonation.⁹⁻¹⁰ Calculated Δq_M values for different sites of ϵ and δ isomers are listed in Table S1 and Table S2 respectively.

Table S2: ϵ -isomer Δq_M values for SO₄²⁻ interactions, in units of fundamental electron charge (e). Deprotonation interactions are highlighted in boldface.

| Keggin | Site 1 | Site 2 |
|--------------------------------|-------------|--------|
| ϵ -GeAl ₁₂ | 0.67 | 0.39 |
| ϵ -Al ₁₃ | 0.41 | 0.34 |

Table S3: δ -isomer Δq_M values for SO₄²⁻ interactions, in units of fundamental electron charge (e). Deprotonation interactions are highlighted in boldface.

ABSTRACT: Keggin-type polyaluminum cations belong to a unique class of polyoxometalates (POMs) with their large positive charge, hydroxo bridges, and divergent isomerization/oligomerization. Previously reported oligomerizations of the polyaluminum cations were driven solely by the δ -Keggin isomer, which created Al_{26} , Al_{30} , and Al_{32} dimeric species. We herein report the isolation of largest ever Keggin-type structure for this system through a unique mode of self-condensation among four ϵ - GeAl_{12}^{8+} to form $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}]^{21+}$ (**Ge₄Al₄₈**). Elemental analysis confirms the Ge^{4+} substitution, and dynamic light scattering experiments indicated that these larger species exist in the thermally aged solutions. DFT calculations have revealed that a single atom Ge substitution in tetrahedral site of ϵ - Al_{13}^{7+} is the key for the formation this cluster because it activates the deprotonation at certain octahedral sites to assist self-condensation in a specific mode.

Since the discovery of Keggin-type polyoxometalates (POMs) in 1933,¹ chemists and material scientists have been fascinated by their unique structural features and applications in energy, medicine, and water purification. The Keggin topology was first identified as a phosphotungstate and contains a central tetrahedrally coordinated cation encapsulated by 12 additional metal octahedra that are bridged through OH^- or O^{2-} groups. The exterior metal cations can connect via shared edges or corners, which leads to five different isomeric (α , β , γ , δ , and ϵ) forms. The chemical diversity for anionic POMs is vast, with the five Keggin isomers formed by octahedrally coordinated V, Mo, W, Nb, and Ta ions encapsulating P, Si, Ge, or As cations.² Structural topologies associated with cationic aluminum-based POMs are notably less diverse, with over 90% of the known species related to the δ -, and ϵ -Keggin topology cations. Chemical diversity for the cationic aluminum POMs are also much more limited than what is observed for the anionic spe-

cies, with only Ga^{3+} and Ge^{4+} full substitution reported for the tetrahedral position and Ga^{3+} and Cr^{3+} partial substitution reported in octahedral position.³⁻⁶ The chemical diversity of the Keggin-topology and the reactivity of these nanoscale clusters has resulted in their use within industrial catalysis and water purification.⁷⁻⁹ Additional efforts are ongoing to explore their use as metallodrugs for cancer treatment¹⁰, electrodes for Li^+ batteries and energy storage¹¹⁻¹², multifunctional sensor¹³ and redox-based nonvolatile memory materials¹⁴. The metal oxo Keggin clusters containing aluminum, iron and others have also been found in natural systems and believe to control different geochemical processes.¹⁵⁻¹⁷

Keggin isomers can also undergo additional hydrolysis reactions or coordination with linkers that result in the formation of larger (>1 nm) oligomers. For the anionic POMs, formation of lacunary structures based upon the α - and β -Keggin motif results in the formation of these larger clusters, with the Wells-Dawson topology as a well-known example. Additional linkages occur through use of either organic linkers¹⁸ or octahedral/heteroatom substitution¹⁸ to create an array of larger anionic POMs based upon two to four Keggin clusters. For polyaluminum Keggin cations, the δ -isomer is the only known synthon and either condenses to form the Al_{26} species or bridges through additional aluminum octahedra to create only two additional topologies (Al_{30} or Al_{32}).¹⁹⁻²⁰ Currently, the largest known cationic POM topologies contains only contains two Keggin units and reflects a lack of understanding on the condensation process within the Al^{3+} system.

Previous studies have demonstrated that heteroatom substitution is important for the oligomerization process and can lead to a new understanding of the condensation process for cationic POMs. For example, Mothé-Estevés *et al.*, indicated that octahedral substitution in Keggin units within anionic POMs can enhance formation of reversible H-bond with other units, which further can condensate into bridging oxygen bond between two metals.²¹ This strategy has been employed to synthesize trimers²²⁻²³ and tetramers²⁴⁻³⁰ of lacunary or tri-lacunary Keggin units within polyanionic

Figure 1. (a) Polyhedra representation of NaGe₄Al₄₈²¹⁺ Keggin cluster with Al³⁺, Ge⁴⁺ and Na⁺ represented in blue, purple, and yellow, respectively. (b) Ball and stick representation for the formation of NaGe₄Al₄₈²¹⁺ from individual ε-GeAl₁₂⁸⁺ building block. The surface H₂O groups that have undergone self-condensation are depicted by translucent red spheres.

POMs. In the case of cationic systems, previous computational work³¹ and experimental observations³²⁻³³ demonstrated that tetrahedral heteroatom substitution at center of Al₁₃⁷⁺ Keggin can tune the chemical behavior of terminal H₂O groups attached to octahedral metal ions. This surface reactivity is vital to the condensation process and may be utilized as synthetic strategy in Al³⁺ Keggin systems to generate larger POMs with novel chemical properties.

In the present study, we describe the synthesis and characterization of a giant (~2.4 nm) Keggin-type aluminum oxo polycation [NaGe₄O₁₆Al₄₈(OH)₁₀₈(H₂O)₂₄]²¹⁺ (**Ge₄Al₄₈**) composed of four ε-GeAl₁₂ Keggin units, without the use of lacunary structures or organic linkers. Additional investigations of the solution phase using Dynamic Light Scattering (DLS) provides evidence of the larger cluster within the solution phase. Density Functional Theory (DFT) calculations also provide an energetic understanding of the formation pathway and additional insights into the role of the counterions in the hydrolysis and condensation processes.

The Ge₄Al₄₈ cluster was synthesized by thermal aging of an aqueous solution containing Al³⁺ and Ge⁴⁺ cation. Initially, a mixed Al³⁺/Ge⁴⁺ solution was partially hydrolyzed at 80 °C, which is the standard procedure for forming the [GeO₄Al₁₂(OH)₂₄(H₂O)₁₂]⁸⁺ (ε-GeAl₁₂) Keggin.⁴ Evaporation of the solution at this point with addition of selenate anions results in the crystallization of the [GeO₄Al₁₂(OH)₂₄(H₂O)₁₂](SeO₄)₄ • 14 H₂O phase. Additional thermal aging of this solution at 90 °C for seven days, followed by addition of the 2,6-naphthalenedisulfonate (2,6-NDS) ion yielded small, transparent crystals of [NaGe₄O₁₆Al₄₈(OH)₁₀₈(H₂O)₂₄](2,6-NDS)₇Cl₇(H₂O)₄₅ with approximate yields of 15% based on Al³⁺.

Structural features of the solid-state material was analyzed using single crystal X-ray diffraction and indicated that the Ge₄Al₄₈ cluster is based upon the ε-Keggin unit. Each ε-isomer is composed of a tetrahedral Ge(O)₄ unit surrounded by 12 Al(OH)₆ octahedra that are connected via edge-sharing μ₂-OH groups between

Al₃(OH)₆(H₂O)₃ trimers (Fig. 1). The Ge-O bond distances ranged from 1.760(11) to 1.806(10) Å and are similar to the isolated ε-GeAl₁₂⁸⁺ Keggin (Ge-O = 1.809(8) Å).⁴ **Ge₄Al₄₈** is formed when four ε-GeAl₁₂ units are linked via twelve μ₂-OH bridging groups (two linkages per trimeric unit) in a tetrahedral (*T_d*) arrangement. A 0.9 nm cavity exists at the center of the **Ge₄Al₄₈** cluster, but X-ray diffraction could only identify a single Na⁺ cation within this space. The [Na(Ge₄Al₄₈)]²¹⁺ unit is charge balanced by seven 2,6-naphthalenedisulfonate and seven chloride ions for an overall compound formula of [NaGe₄O₁₆Al₄₈(OH)₁₀₈(H₂O)₂₄](2,6-NDS)₇Cl₇(H₂O)₄₅. The 2,6-naphthalenedisulfonate ions are arranged within two separate channels in the [010] and [101] directions. These anions aid in the crystallization of the Ge₄Al₄₈ cluster by engaging in both π-π interaction between the naphthalene rings and electrostatics with the positively charged clusters.¹⁹

The structural topology observed in **Ge₄Al₄₈** is unique because it is the only giant cationic tetrahedron formed through non-lacunary ε-isomers within the POM family of compounds. A handful of large tetrahedron forms have been reported for polyanions, but they only occurs through Dawson lacunary clusters^{29-30, 34} or other lacunary fragments.^{27-28, 35-36} Only one compound reported by Hussain *et al.* contains direct linkages between the β-Keggin isomer [(β-Ti₂SiW₁₀O₃₉)₄]²⁴⁻ but forms a circular wheel instead of a larger tetrahedral unit.³⁷ The wheel also contains three K⁺ ions, one present in the central cavity and another two act as “wheel caps”. The presence of the Ti⁴⁺ cations as a surface reactive species was found to be key to the formation of this larger Keggin-based cluster as it provides an avenue for additional hydrolysis and condensation.

Additional chemical characterization of this system confirms the heteroatom content and the presence of the oligomerized **Ge₄Al₄₈** cluster in thermally aged solutions. Solid-state crystals were dissolved in an acidic solution and the elemental content was analyzed by ICP-MS. The theoretical Al:Ge ratio for the Ge₄Al₄₈²⁰⁺ cluster is 12 and our experimental value was 12.43 ± 0.45 (Table S1), which is within error of the expected value. Formation

of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer in solution was also supported by the hydrodynamic diameter measurement of Keggin ions by Dynamic Light Scattering (DLS) measurements (Fig. 2). The unaged, partially hydrolyzed $\text{Ge}^{4+}/\text{Al}^{3+}$ stock solution displays one peak in the

Figure 2. Particle size distribution from DLS of as prepared GeAl_{12} solution and after aging 7 days at 90 °C.

DLS plot with a peak centroid at 1.2 nm. This value is consistent with the theoretical value for the size of $\epsilon\text{-GeAl}_{12}$ cluster. Upon thermal aging, the single peak in the DLS plot broadens and shifts to a higher particle size. The peak centroid in the aged solutions is at 2.8 nanometers, which is now consistent with the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer.

One important aspect of the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer is the divergence from the previously studied Al^{3+} and $\text{Al}^{3+}/\text{Ga}^{3+}$ systems.^{5, 19} Oligomerization within these systems initially begins with the conversion of the ϵ -Keggin form to the δ -isomer. Previous studies have postulated that rotated trimer of the $\delta\text{-Al}_{13}$ and $\delta\text{-GaAl}_{12}$ is a reactive site, which can form larger clusters by self-condensation $\mu_2\text{-OH}$ bridging or use of additional Al^{3+} octahedra to link fragments together.^{5, 19} In the $\text{Al}^{3+}/\text{Ge}^{4+}$ system there is no experimental evidence for the formation of the δ -isomer and the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer offers the glimpse into the structural features of the condensation product within this system. Our initial hypotheses regarding the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer is that the $\epsilon\text{-GeAl}_{12}$ synthon has reactive terminal H_2O groups that allow for condensation into $\text{Ge}_4\text{Al}_{48}^{20+}$. We use Density Functional Theory (DFT) calculations to test this hypothesis and provide additional insights into the system.

The surface reactivity of the ϵ - and δ -isomers for Al_{13} and GeAl_{12} clusters was investigated to further evaluate the condensation process. We have previously used modeled outer-sphere adsorption of sulfate as a probe of cluster surface reactivity. In some cases, the adsorption leads to the deprotonation of different surface

sites over the course of geometry optimization, thus identifying relatively labile protons. While sulfate anions are not present in the thermally aged solution, they are effective as a probe adsorbate to identify the most acidic proton that can act as the driving force for the formation of this tetramer. This modeling approach has been applied to the $\delta\text{-GaAl}_{12}$ cluster, where it was used to establish that the driving force for oligomerization is deprotonation of the rotated trimer.⁵ Here, we again use modeled adsorption with a sulfate probe to study how Ge^{4+} substitution effects on surface reactivity (in terms of adsorption energies and ease of deprotonation) of the ϵ and δ -isomers for the Al_{13} and GeAl_{12} and the formation of $\text{Ge}_4\text{Al}_{48}^{20+}$ (additional details in SI).

We model sulfate-cluster interactions starting from two chemically-distinct starting configurations (referred to as Sites 1 and 2) for $\epsilon\text{-Al}_{13}$ and $\epsilon\text{-GeAl}_{12}$ Keggin clusters (Fig. 3b). In Site 1, the anion is positioned to interact with two terminal $\eta_1\text{-H}_2\text{O}$ groups on two different $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ trimers, corresponding to point where the $\epsilon\text{-GeAl}_{12}$ Keggin clusters oligomerize into the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer. In Site 2, the sulfate anion can engage with a mixture of $\eta_1\text{-H}_2\text{O}$ and $\mu_2\text{-OH}$ groups on the surface of one $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ trimer unit. We compare changes in the Mulliken population (Δq_m) to deprotonation events. Of the four ϵ -Keggin interactions, only Site 1 sulfate interactions with $\epsilon\text{-GeAl}_{12}$ (Table S2 and Figure 2) result in deprotonation and a Δq_m value greater than 0.50 e. All other interactions have Δq_m values of less than 0.50 e and did not exhibit deprotonation, similar to previous observations on Keggin-anion interactions.^{5, 31, 38}

To bridge the understanding between isomers and heteroatom identity with regard to condensation reactions, we also assessed the δ -isomers for GeAl_{12} and Al_{13} using the sulfate anion as our probe adsorbate (Table S3 and Figure S1). The ϵ -isomer has four equivalent edge-sharing trimers whereas the δ -isomer has three edge-sharing trimers and one rotated, corner-sharing trimer. The number of corner- versus edge-trimers influences the surface reactivity of the nanocluster. For the δ -isomer, three chemically distinct sites can be found on Keggin surface that correspond to interactions with $\eta_1\text{-H}_2\text{O}$ and $\mu_2\text{-OH}$ groups on the different $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ units. For $\delta\text{-Al}_{13}$, deprotonation only occurs associated with the reactive trimer (rotated $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ group), whereas higher charge transfer and deprotonation is observed for all sites on the $\delta\text{-GeAl}_{12}$ clusters (Table S3). Our calculation confirms that deprotonation events for the reactive site on the $\delta\text{-Al}_{13}$ leads to the formation of Al_{26} , Al_{30} or Al_{32} . However, the high charge transfer on all surface sites associate the $\delta\text{-GeAl}_{12}$ cluster suggests that random condensation will occur and likely form amorphous precipitates.

In summary, we have reported the synthesis and characterization of a new cationic POM tetramer ($\text{Ge}_4\text{Al}_{48}^{20+}$) composed solely of ϵ -Keggin units without any lacunary features or organic linkers. DLS experiments indicate that this large tetramer occurs in partially hydrolyzed solutions containing Al^{3+} and Ge^{4+} after thermal aging for seven days. DFT calculations indicated that Ge^{4+} substitution at the central tetrahedral site of the Keggin topology is key to the formation of the tetramer because it specifically deprotonates $\eta_1\text{-H}_2\text{O}$ to form symmetric $\mu_2\text{-OH}$ bridges, which can be linked to the formation of the tetramer. This work has demonstrated the importance of the metal cation identity to control stability and reactivity, even when it is located at the center of the Keggin cluster. More broadly, it provides additional details in the nucleation process of metal oxide and hydroxide phases from POM synthons that can be used to provide additional controls on the development of functional materials.

Figure 3. Different surface sites of ϵ - GeAl₁₂ and ϵ - Al₁₃ interacting with SO₄²⁻ ion. The abstracted proton is highlighted with a green circle. Blue and purple polyhedra are used to represent Al and Ge atoms, respectively. Red, yellow and white balls are used to represent O, S, and H atoms, respectively.

Author Contributions

TZF and SEM provided resources, support and funding to carry-out the study. MS and JAS did the synthesis experiment. MS did all the chemical characterization, crystallography and experimental data analysis. JLB conducted all of the DFT calculations. MS and JLB prepared the initial draft of manuscript. All authors contributed to the writing and editing of final manuscript for the submission.

Notes

The authors declare no competing financial interests.

ACKNOWLEDGMENT

SEM acknowledges computational resources provided by the University of Iowa. This work used the Extreme Science and Engineering Discovery Environment (XSEDE),³⁹ which is supported by the National Science Foundation grant number ACI-1548562 though allocation TG-GEO160006. We acknowledge Prof. Aliasger Salem and Dr. Lr Jaidev Chakka (UI college of Pharmacy) for their help regarding DLS experiment. TZF and MS also acknowledge American Crystallographic Association (ACA) summer school 2019 at Northwestern University for their travel support to teach MS advanced-level crystallography. JLB acknowledges support from the University of Iowa's Dissertation Writing Fellowship.

ABSTRACT: Keggin-type polyaluminum cations belong to a unique class of polyoxometalates (POMs) with their large positive charge, hydroxo bridges, and divergent isomerization/oligomerization. Previously reported oligomerizations of the polyaluminum cations were driven solely by the δ -Keggin isomer, which created Al_{26} , Al_{30} , and Al_{32} dimeric species. We herein report the isolation of largest ever Keggin-type structure for this system through a unique mode of self-condensation among four ϵ - GeAl_{12}^{8+} to form $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}]^{21+}$ (**$\text{Ge}_4\text{Al}_{48}$**). Elemental analysis confirms the Ge^{4+} substitution, and dynamic light scattering experiments indicated that these larger species exist in the thermally aged solutions. DFT calculations have revealed that a single atom Ge substitution in tetrahedral site of ϵ - Al_{13}^{7+} is the key for the formation this cluster because it activates the deprotonation at certain octahedral sites to assist self-condensation in a specific mode.

Since the discovery of Keggin-type polyoxometalates (POMs) in 1933,¹ chemists and material scientists have been fascinated by their unique structural features and applications in energy, medicine, and water purification. The Keggin topology was first identified as a phosphotungstate and contains a central tetrahedrally coordinated

cation encapsulated by 12 additional metal octahedra that are bridged through OH^- or O^{2-} groups. The exterior metal cations can connect via shared edges or corners, which leads to five different isomeric (α , β , γ , δ , and ϵ) forms. The chemical diversity for anionic POMs is vast, with the five Keggin isomers formed by octahedrally coordinated V, Mo, W, Nb, and Ta ions incapsulating P, Si, Ge, or As cations.² Structural topologies associated with cationic aluminum-based POMs are notably less diverse, with over 90% of the known species related to the δ -, and ϵ -Keggin topology cations. Chemical diversity for the cationic aluminum POMs are also much more limited than what is observed for the anionic species, with only Ga^{3+} and Ge^{4+} full substitution reported for the tetrahedral position and Ga^{3+} and Cr^{3+} partial substitution reported in octahedral position.³⁻⁶ The chemical diversity of the Keggin-topology and the reactivity of these nanoscale clusters has resulted in their use within industrial catalysis and water purification.⁷⁻⁹ Additional efforts are ongoing to explore their use as metallodrugs for cancer treatment¹⁰, electrodes for Li^+ batteries and energy storage¹¹⁻¹², multifunctional sensor¹³ and redox-based nonvolatile memory materials¹⁴. The metal oxo Keggin clusters containing aluminum, iron and others have also been found in natural systems and believe to control different geochemical processes.¹⁵⁻¹⁷

Keggin isomers can also undergo additional hydrolysis reactions or coordination with linkers that result in the formation of larger (>1 nm) oligomers. For the anionic POMs, formation of lacunary structures based upon the α - and β -Keggin motif results in the formation of these larger clusters, with the Wells-Dawson topology as a well-known example. Additional linkages occur through use of either organic linkers¹⁸ or octahedral/heteroatom substitution¹⁸ to create an array of larger anionic POMs based upon two to four Keggin clusters. For polyaluminum Keggin cations, the δ -isomer is the only known synthon and either condenses to form the Al_{26} species or bridges through additional aluminum octahedra to create only two additional topologies (Al_{30} or Al_{32}).¹⁹⁻²⁰ Currently, the largest known cationic

POM topologies contains only contains two Keggin units and reflects a lack of understanding on the condensation process within the Al^{3+} system.

Previous studies have demonstrated that heteroatom substitution is important for the oligomerization process and can lead to a new understanding of the condensation process for cationic POMs. For example, Mothé-Esteves *et al.*, indicated that octahedral substitution in Keggin units within anionic POMs can enhance formation of reversible H-bond with other units, which further can condensate into bridging oxygen bond between two metals.²¹ This strategy has been employed to synthesize trimers²²⁻²³ and tetramers²⁴⁻³⁰ of lacunary or tri-lacunary Keggin units within polyanionic

Figure 1. (a) Polyhedra representation of $\text{NaGe}_4\text{Al}_{48}^{21+}$ Keggin cluster with Al^{3+} , Ge^{4+} and Na^+ represented in blue, purple, and yellow, respectively. (b) Ball and stick representation for the formation of $\text{NaGe}_4\text{Al}_{48}^{21+}$ from individual $\epsilon\text{-GeAl}_{12}^{8+}$ building block. The surface H_2O groups that have undergone self-condensation are depicted by translucent red spheres.

POMs. In the case of cationic systems, previous computational work³¹ and experimental observations³²⁻³³ demonstrated that tetrahedral heteroatom substitution at center of Al_{13}^{7+} Keggin can tune the chemical behavior of terminal H_2O groups attached to octahedral metal ions. This surface reactivity is vital to the condensation process and may be utilized as synthetic strategy in Al^{3+} Keggin systems to generate larger POMs with novel chemical properties.

In the present study, we describe the synthesis and characterization of a giant (~2.4 nm) Keggin-type aluminum oxo polycation $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}]^{21+}$ ($\text{Ge}_4\text{Al}_{48}$) composed of four $\epsilon\text{-GeAl}_{12}$ Keggin units, without the use of lacunary structures or organic linkers. Additional investigations of the solution phase using

Dynamic Light Scattering (DLS) provides evidence of the larger cluster within the solution phase. Density Functional Theory (DFT) calculations also provide an energetic understanding of the formation pathway and additional insights into the role of the counterions in the hydrolysis and condensation processes.

The $\text{Ge}_4\text{Al}_{48}$ cluster was synthesized by thermal aging of an aqueous solution containing Al^{3+} and Ge^{4+} cation. Initially, a mixed $\text{Al}^{3+}/\text{Ge}^{4+}$ solution was partially hydrolyzed at 80 °C, which is the standard procedure for forming the $[\text{GeO}_4\text{Al}_{12}\text{OH}_{24}\text{H}_2\text{O}_{12}]^{8+}$ ($\epsilon\text{-GeAl}_{12}$) Keggin.⁴ Evaporation of the solution at this point with addition of selenate anions results in the crystallization of the $[\text{GeO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}]$ (SeO_4)₄ • 14 H_2O phase. Additional thermal aging of

this solution at 90 °C for seven days, followed by addition of the 2,6-naphthalenedisulfonate (2,6-NDS) ion yielded small, transparent crystals of $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}](2,6\text{-NDS})_7\text{Cl}_7(\text{H}_2\text{O})_{45}$ with approximate yields of 15% based on Al^{3+} .

Structural features of the solid-state material was analyzed using single crystal X-ray diffraction and indicated that the $\text{Ge}_4\text{Al}_{48}$ cluster is based upon the ϵ -Keggin unit. Each ϵ -isomer is composed of a tetrahedral $\text{Ge}(\text{O})_4$ unit surrounded by 12 $\text{Al}(\text{OH})_6$ octahedra that are connected via edge-sharing $\mu_2\text{-OH}$ groups between $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ trimers (Fig. 1). The Ge-O bond distances ranged from 1.760(11) to 1.806(10) Å and are similar to the isolated $\epsilon\text{-GeAl}_{12}^{8+}$ Keggin ($\text{Ge-O} = 1.809(8)$ Å).⁴ **$\text{Ge}_4\text{Al}_{48}$** is formed when four $\epsilon\text{-GeAl}_{12}$ units are linked via twelve $\mu_2\text{-OH}$ bridging groups (two linkages per trimeric unit) in a tetrahedral (T_d) arrangement. A 0.9 nm cavity exists at the center of the **$\text{Ge}_4\text{Al}_{48}$** cluster, but X-ray diffraction could only identify a single Na^+ cation within this space. The $[\text{Na}(\text{Ge}_4\text{Al}_{48})]^{21+}$ unit is charge balanced by seven 2,6-naphthalenedisulfonate and seven chloride ions for an overall compound formula of $[\text{NaGe}_4\text{O}_{16}\text{Al}_{48}(\text{OH})_{108}(\text{H}_2\text{O})_{24}](2,6\text{-NDS})_7\text{Cl}_7(\text{H}_2\text{O})_{45}$. The 2,6-naphthalenedisulfonate ions are arranged within two separate channels in the [010] and [101] directions. These anions aid in the crystallization of the $\text{Ge}_4\text{Al}_{48}$ cluster by engaging in both $\pi\text{-}\pi$ interaction between the naphthalene rings and electrostatics with the positively charged clusters.¹⁹

The structural topology observed in **$\text{Ge}_4\text{Al}_{48}$** is unique because it is the only giant cationic tetrahedron formed through non-lacunary ϵ -isomers within the POM family of compounds. A handful of large tetrahedron forms have been reported for polyanions, but they only occur through Dawson lacunary clusters^{29-30, 34} or other lacunary fragments.^{27-28, 35-36} Only one compound reported by Hussain *et al.* contains direct linkages between the β -Keggin isomer $[(\beta\text{-Ti}_2\text{SiW}_{10}\text{O}_{39})_4]^{24-}$ but forms a circular wheel instead of a larger tetrahedral unit.³⁷ The wheel also contains three K^+ ions, one present in the central cavity and another two act as “wheel caps”. The presence of the Ti^{4+} cations as a surface reactive species was found to be key to the formation of this larger Keggin-based cluster as it provides an avenue for additional hydrolysis and condensation.

Additional chemical characterization of this system confirms the heteroatom content and the presence of the oligomerized **$\text{Ge}_4\text{Al}_{48}$** cluster in thermally aged solutions. Solid-state crystals were dissolved in an acidic solution and the elemental content was analyzed by ICP-MS. The theoretical Al:Ge ratio for the $\text{Ge}_4\text{Al}_{48}^{20+}$ cluster is 12 and our experimental value was 12.43 ± 0.45 (Table S1), which is within error of the expected value. Formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer in solution was also supported by the hydrodynamic diameter measurement of Keggin ions by Dynamic Light Scattering (DLS) measurements (Fig. 2). The

unaged, partially hydrolyzed $\text{Ge}^{4+}/\text{Al}^{3+}$ stock solution displays one peak in the

Figure 2. Particle size distribution from DLS of as prepared GeAl_{12} solution and after aging 7 days at 90 °C.

DLS plot with a peak centroid at 1.2 nm. This value is consistent with the theoretical value for the size of $\epsilon\text{-GeAl}_{12}$ cluster. Upon thermal aging, the single peak in the DLS plot broadens and shifts to a higher particle size. The peak centroid in the aged solutions is at 2.8 nanometers, which is now consistent with the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer.

One important aspect of the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer is the divergence from the previously studied Al^{3+} and $\text{Al}^{3+}/\text{Ga}^{3+}$ systems.^{5, 19} Oligomerization within these systems initially begins with the conversion of the ϵ -Keggin form to the δ -isomer. Previous studies have postulated that rotated trimer of the $\delta\text{-Al}_{13}$ and $\delta\text{-GaAl}_{12}$ is a reactive site, which can form larger clusters by self-condensation $\mu_2\text{-OH}$ bridging or use of additional Al^{3+} octahedra to link fragments together.^{5, 19} In the $\text{Al}^{3+}/\text{Ge}^{4+}$ system there is no experimental evidence for the formation of the δ -isomer and the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer offers the glimpse into the structural features of the condensation product within this system. Our initial hypotheses regarding the formation of the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer is that the $\epsilon\text{-GeAl}_{12}$ synthon has reactive terminal H_2O groups that allow for condensation into $\text{Ge}_4\text{Al}_{48}^{20+}$. We use Density Functional Theory (DFT) calculations to test this hypothesis and provide additional insights into the system.

The surface reactivity of the ϵ - and δ -isomers for Al_{13} and GeAl_{12} clusters was investigated to further evaluate the condensation process. We have previously used modeled outer-sphere adsorption of sulfate as a probe of cluster surface reactivity. In some cases, the adsorption leads to the deprotonation of different surface sites over the course of geometry optimization, thus identifying relatively labile protons. While sulfate anions are not present in the thermally aged solution, they are effective as a probe adsorbate to identify the most acidic proton that can act as the driving force for the formation of this tetramer. This modeling approach has been applied to the δ - GaAl_{12} cluster, where it was used to establish that the driving force for oligomerization is deprotonation of the rotated trimer.⁵ Here, we again use modeled adsorption with a sulfate probe to study how Ge^{4+} substitution effects on surface reactivity (in terms of adsorption energies and ease of deprotonation) of the ϵ and δ -isomers for the Al_{13} and GeAl_{12} and the formation of $\text{Ge}_4\text{Al}_{48}^{20+}$ (additional details in SI).

We model sulfate-cluster interactions starting from two chemically-distinct starting configurations (referred to as Sites 1 and 2) for ϵ - Al_{13} and ϵ - GeAl_{12} Keggin clusters (Fig. 3b). In Site 1, the anion is positioned to interact with two terminal η_1 - H_2O groups on two different $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ trimers, corresponding to point where the ϵ - GeAl_{12} Keggin clusters oligomerize into the $\text{Ge}_4\text{Al}_{48}^{20+}$ tetramer. In Site 2, the sulfate anion can engage with a mixture of η_1 - H_2O and μ_2 -OH groups on the surface of one $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ trimer unit. We compare changes in the Mulliken population (Δq_m) to deprotonation events. Of the four ϵ -Keggin interactions, only Site 1 sulfate interactions with ϵ - GeAl_{12} (Table S2 and Figure 2) result in deprotonation and a Δq_m value greater than 0.50 e. All other interactions have Δq_m values of less than 0.50 e and did not exhibit deprotonation, similar to previous observations on Keggin-anion interactions.^{5, 31, 38}

To bridge the understanding between isomers and heteroatom identity with regard to condensation reactions, we also assessed the δ -

isomers for GeAl_{12} and Al_{13} using the sulfate anion as our probe adsorbate (Table S3 and Figure S1). The ϵ -isomer has four equivalent edge-sharing trimers whereas the δ -isomer has three edge-sharing trimers and one rotated, corner-sharing trimer. The number of corner- versus edge-trimers influences the surface reactivity of the nanocluster. For the δ -isomer, three chemically distinct sites can be found on Keggin surface that correspond to interactions with η_1 - H_2O and μ_2 -OH groups on the different $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ units. For δ - Al_{13} , deprotonation only occurs associated with the reactive trimer (rotated $\text{Al}_3(\text{OH})_6(\text{H}_2\text{O})_3$ group), whereas higher charge transfer and deprotonation is observed for all sites on the δ - GeAl_{12} clusters (Table S3). Our calculation confirms that deprotonation events for the reactive site on the δ - Al_{13} leads to the formation of Al_{26} , Al_{30} or Al_{32} . However, the high charge transfer on all surface sites associate the δ - GeAl_{12} cluster suggests that random condensation will occur and likely form amorphous precipitates.

In summary, we have reported the synthesis and characterization of a new cationic POM tetramer ($\text{Ge}_4\text{Al}_{48}^{20+}$) composed solely of ϵ -Keggin units without any lacunary features or organic linkers. DLS experiments indicate that this large tetramer occurs in partially hydrolyzed solutions containing Al^{3+} and Ge^{4+} after thermal aging for seven days. DFT calculations indicated that Ge^{4+} substitution at the central tetrahedral site of the Keggin topology is key to the formation of the tetramer because it specifically deprotonates η_1 - H_2O to form symmetric μ_2 -OH bridges, which can be linked to the formation of the tetramer. This work has demonstrated the importance of the metal cation identity to control stability and reactivity, even when it is located at the center of the Keggin cluster. More broadly, it provides additional details in the nucleation process of metal oxide and hydroxide phases from POM synthons that can be used to provide additional controls on the development of functional materials.

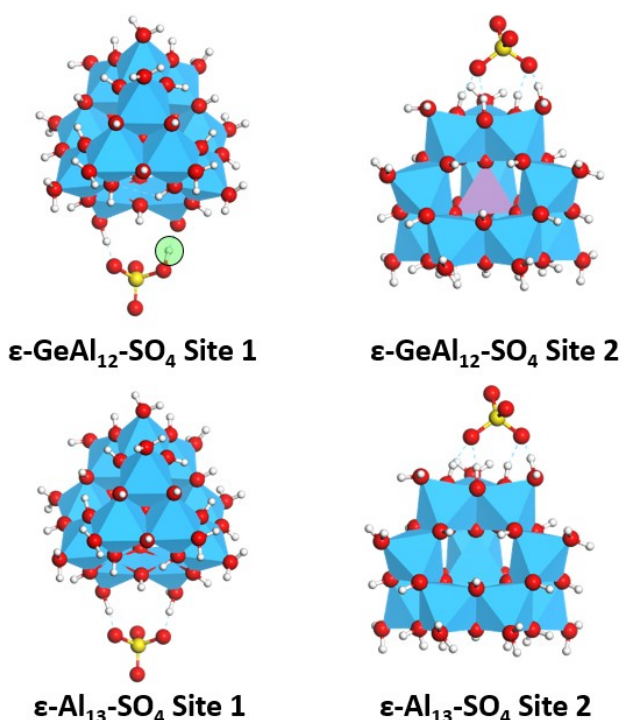

Figure 3. Different surface sites of ϵ - GeAl₁₂ and ϵ - Al₁₃ interacting with SO₄²⁻ ion. The abstracted proton is highlighted with a green circle. Blue and purple polyhedra are used to represent Al and Ge atoms, respectively. Red, yellow and white balls are used to represent O, S, and H atoms, respectively.

Supporting Information

A supporting information file in pdf format is available free of charge on the ACS Publications website (<http://pubs.acs.org>). The supporting information file contains experimental details, result of elemental analysis, result of computational calculation and additional figures. Additional crystallographic information files can be found on the Cambridge Structural Database by requesting deposition numbers 2027043.

AUTHOR INFORMATION

Corresponding Author

*Tori Z. Forbes: tori-forbes@uiowa.edu

Author Contributions

TZF and SEM provided resources, support and funding to carry-out the study. MS and JAS did the synthesis experiment. MS did all the chemical characterization, crystallography and experimental data analysis. JLB conducted all of the DFT calculations. MS and JLB prepared the initial draft of manuscript. All authors contributed to the writing and editing of final manuscript for the submission.

Notes

The authors declare no competing financial interests.

ACKNOWLEDGMENT

SEM acknowledges computational resources provided by the University of Iowa. This work used the Extreme Science and Engineering Discovery Environment (XSEDE),³⁹ which is supported by the National Science Foundation grant number ACI-1548562 through allocation TG-GEO160006. We acknowledge Prof. Aliasger Salem and Dr. Lr Jaidev Chakka (UI college of Pharmacy) for their help regarding DLS experiment. TZF and MS also acknowledge American Crystallographic Association (ACA) summer school 2019 at Northwestern University for their travel support to teach MS advanced-level crystallography. JLB acknowledges support from the University of Iowa's Dissertation Writing Fellowship.
